Design and Prototyping of a New Balancing Mechanism for Spatial Parallel Manipulators

This paper proposes a new solution to the problem of torque minimization of spatial parallel manipulators. The suggested approach involves connecting a secondary mechanical system to the initial structure, which generates a vertical force applied to the manipulator platform. Two versions of the added force are considered: constant and variable. The conditions for optimization are formulated by the minimization of the root-mean-square values of the input torques. The positioning errors of the unbalanced and balanced parallel manipulators are provided. It is shown that the elastic deformations of the manipulator structure, which are due to the payload, change the altitude and the inclination of the platform. A significant reduction of these errors is achieved by using the balancing mechanism. The efficiency of the suggested solution is illustrated by numerical simulations and experimental verifications. The prototype of the suggested balancing mechanism for the Delta robot is also presented. [DOI: 10.1115/1.2901057]

Keywords: balancing, torque compensation, parallel mechanisms, Delta robot

1 Introduction

A mechanism of parallel architecture is statically balanced if its potential energy is constant for all possible configurations. This means that the mechanism is statically stable for any configuration; i.e., zero actuator torques due to the static loads are required. For static balancing of robot mechanisms, different approaches and solutions have been developed and documented [3–41]. The balancing schemes for robotic systems can be systematized by means of balancing (Table 1): counterweight (group A); spring (group B); pneumatic or hydraulic cylinder, electromagnetic device, etc. (group C). Each group can be presented by the following subgroups.

- A1. Balancing by counterweights mounted on the links of the initial system [3–6]. Such balancing is very simple to realize. However, it leads to an important increase of the moving masses of the manipulator and, as a result, its inertia.
- A2. Balancing by counterweights mounted on the auxiliary linkage connected with the initial system [7–10]. Articulated dyads or pantograph mechanism are used as an auxiliary linkage.
- B1. Balancing by springs jointed directly with manipulator links [11–14].
- B2. Balancing by using a cable and pulley arrangement [15–18]. Such an approach allows zero free length springs to be used, which is more favorable for the realization of a complete balancing.

Balancing by using an auxiliary mechanism can be presented in the following manner:

Contributed by the Mechanisms and Robotics Committee of ASME for publication in the JOURNAL OF MECHANICAL DESIGN. Manuscript received February 15, 2007; final manuscript received July 2, 2007; published online May 22, 2008. Review conducted by José M. Rico.

- B3.1. Balancing by using an auxiliary linkage [19-29]
- B3.2. Balancing by using a cam mechanism [30-33]
- B3.3. Balancing by using gear train [34–37]
- C. Balancing by using pneumatic or hydraulic cylinders, which are connected to manipulator links [38] or directly with the moving platform [39]. There is a balancing approach based on counterweights, which are fluid reservoirs. Continuous balancing is achieved by the pumping of the fluid from the first reservoir counterweight to the second [40]. Electromagnetic effects were also used for balancing [41].

The literature review showed that many balancing methods are applicable for planar parallel manipulators. However, the balancing of spatial parallel architectures is a complicated problem because it can be achieved either by an unavoidable increase of the total mass of moving links [4,9] or by a considerably complicated design of the initial parallel mechanism [42]. Let us consider this problem for the Delta robot.

The Delta robot [43] was developed for high-speed manipulation, and it is well known in the electronics, food, and pharmaceutical sectors as a reliable system with fast execution of light-duty tasks. However, in recent years, much attention has been paid to the increasing number of possible industrial applications, such as the manipulation of medical devices (Fig. 1).

In this case, the displacement speed of the platform is not essential because there is no need for productivity acceleration. However, as a result of the increased mass of the platform (about 70 kg), the input torques became important. Thus, it became evident that the platform's mass must be balanced. In this case, the traditional approaches with counterweights and springs mounted on the moving links are not applicable. The Delta robot has a complex structure, and after such balancing it becomes either very heavy or a complicated assembly with several complementary articulated dyads. That is why another means for the solution of this problem is proposed. It consists in the addition of a secondary mechanism between the manipulator base and the moving plat-

²It should be noted that in the balancing of high-speed mechanisms, the term "static balancing" refers to shaking force cancellation or minimization [1,2]. With regard to the static balancing in robotics, this term differs from the first definition because in this case, the aim of the balancing is the minimization or cancellation of input torques of a mechanical system by means of gravitational force balancing.

Table 1 Balancing schemes for robotic systems

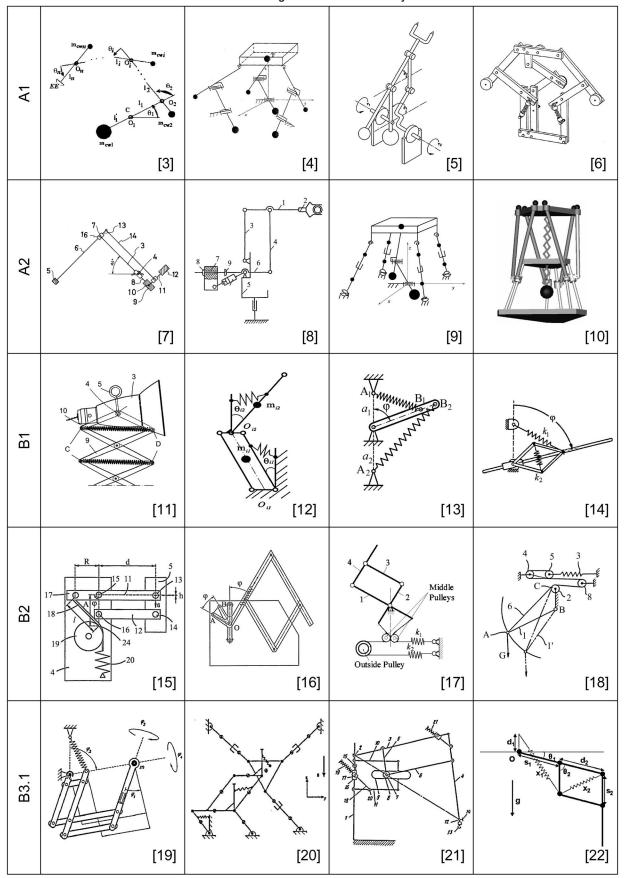

Table 1 (Continued.)

form. This mechanism can create a supplementary vertical force F on the platform to balance the gravitational forces of the robot (Fig. 2).

In this context, a new balancing mechanism for the minimization of the input torque of the spatial parallel manipulators with high weight-carrying capacity is developed.

2 Description of the Balancing Mechanism

The suggested balancing system includes (Fig. 3) a pantograph

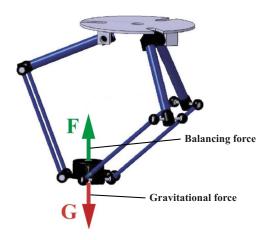

Fig. 2 Principle of balancing

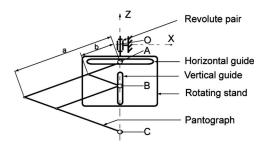

Fig. 3 Simplified scheme of the balancing mechanism

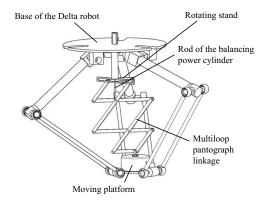

Fig. 4 Delta robot with the balancing mechanism

mechanism mounted on the rotating stand connected with the base. The input points A and B of the pantograph are located in the horizontal and vertical guides of the rotating stand. So, the suggested system has three degrees of freedom: a rotation of the stand about the vertical axis and two translations along the guides. This allows the suggested system to be passive in relation to the Delta robot when point C is connected to the platform.

Point B is also connected to an actuator that produces a vertical force. This vertical force F_B is used for the balancing of the gravitational forces of the spatial parallel robot. It is obvious that the determination of the balancing force $F_B = kF$ takes into account the magnification factor of the pantograph (k=AC/AB=a/b).

Thus, the position of point C is represented by vector $\mathbf{P} = [x,y,z]^T$, and the passive motions of the pantograph are represented by $\mathbf{q} = [r,\theta,Z]^T$. The kinematic relations between \mathbf{P} and \mathbf{q} are the following: $x = (1-k)r\cos\theta$, $y = (1-k)r\sin\theta$, and z = kZ. By differentiating these equations with respect to time, one obtains

$$\dot{\mathbf{q}} = \mathbf{J}^{-1}\mathbf{P} \tag{1}$$

where

$$\dot{\mathbf{P}} = \begin{bmatrix} \dot{x} & \dot{y} & \dot{z} \end{bmatrix}^T \tag{2}$$

$$\dot{\mathbf{q}} = [\dot{r} \quad \dot{\theta} \quad \dot{Z}]^T \tag{3}$$

$$\mathbf{J} = \begin{bmatrix} (1-k)\cos\theta & (k-1)r\sin\theta & 0\\ (1-k)\sin\theta & (1-k)r\cos\theta & 0\\ 0 & 0 & k \end{bmatrix}$$
(4)

where x, y, and z are the coordinates of the platform in the Cartesian space; θ is the angle of the rotating stand of the balancing mechanism, r and Z correspond to the displacements in the horizontal and vertical guides of the balancing mechanism.

It is obvious that the added balancing system cannot follow all trajectories of the parallel robot. For example, if the given trajectory of the parallel robot is composed of two mutually perpendicular straight lines, which intersect at the point of x=y=0, the balancing mechanism cannot execute a continuous motion. In this case, it is necessary to orientate the plane of the pantograph mechanism relative to the **Z** axis. Thus, it is evident that the balancing mechanism must be equipped with a complementary rotating actuator for its orientation in the case of singular trajectories. This complementary actuator may be in operation only for special cases.

It should be noted that in the positions close to the singular trajectories, the secondary mechanism can rotate quickly, and it is necessary to carry out an optimal control of the Delta robot with slow motion.

Figure 4 shows the balancing mechanism, which is implemented in the structure of the Delta robot. A multiloop pantograph

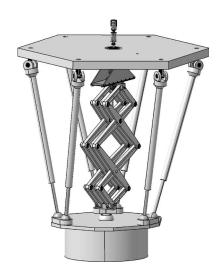

Fig. 5 Stewart platform with implemented balancing system

linkage with several link lengths allows the reduction of the overall size of the balancing mechanism. The size of the pantograph links must be chosen in such a manner that they should not collide with the legs of the Delta robot.

However, it is necessary to note that the suggested balancing mechanism is applicable to many spatial parallel robots from three (3DOF) to six degrees of freedom (6DOF).

Figure 5 shows an example of such an application for the Gough–Stewart platform with an implemented balancing system.

In the proposed design of the Gough–Stewart platform, the payload is balanced by the suggested mechanism. So, the platform becomes a weightless link, and it can be displaced and oriented by low-power linear actuators.

We would like to note some particularity of the balancing of spatial parallel manipulators with 6DOF: If the gravity center of the platform is not situated in the attachment point of the balancing mechanism, a change in the orientation of the platform will move its center of mass, which will lead to a complementary moment. However, our observations showed that this complementary moment will be incomparably less than the initial unbalanced moment.

In the following section, we consider the balancing of the Delta robot by means of the proposed mechanism, and we discuss the minimization of the input torques by a constant or a variable force.

3 Minimization of the Torque by a Constant Force Applied to the Robot Platform

Let us examine two cases: minimization of the torques due to the static loads, i.e., weights of the moving links, and dynamic forces, i.e., inertia forces.

3.1 Minimization of the Torques Due to Static Loads (**Gravitational Forces**). The input torque of the *n*th actuator can be expressed as

$$M_n^{\text{st}} = M_{1n}^{\text{st}} + M_{2n}^{\text{st}} + M_{3n}^{\text{st}} + M_{4n}^{\text{st}}$$
 (5)

where $M_{1n}^{\rm st}$ is the torque due to the gravitational forces of the arms (see Fig. 6), $M_{2n}^{\rm st}$ is the torque due to the parallelograms, $M_{3n}^{\rm st}$ is the torque due to the joints on points B_i , and $M_{4n}^{\rm st}$ is the torque due to the gravity forces of the platform and the medical device. For i, n=1,2,3, for j=1,2,3, $\mathbf{M}_{in}^{\rm st}$ is equal to

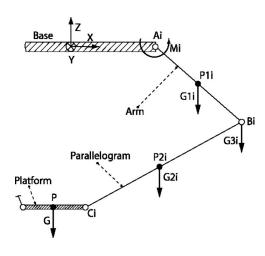

Fig. 6 Gravitational forces for leg i

$$\mathbf{M}_{jn}^{\mathrm{st}}(x,y,z) = \left(\sum_{i=1}^{3} \mathbf{J}_{ji}^{T}(x,y,z) \cdot \mathbf{G}_{ji} \right) \Big|_{n}$$
 (6)

and for n=1,2,3 and j=4, $\mathbf{M}_{4n}^{\mathrm{st}}$ is equal to

$$\mathbf{M}_{4p}^{\mathrm{st}}(x, y, z) = (\mathbf{J}^{T}(x, y, z) \cdot \mathbf{G})|_{p}$$
 (7)

where \mathbf{J}_{1i} is the Jacobian matrix between the point P_{1i} and the actuated variables θ_n , \mathbf{J}_{2i} is the Jacobian matrix between point P_{2i} and the actuated variables θ_n , \mathbf{J}_{3i} is the Jacobian matrix between point B_i and the actuated variables θ_n , \mathbf{J} is the general Jacobian matrix of the robot between point P and the actuated variables θ_n . For i, n=1,2,3, and \mathbf{G} and \mathbf{G}_{ji} are the gravity forces (Fig. 6). The matrix \mathbf{J}_{ji} (j=1,2,3) can be written as

$$\mathbf{J}_{1i} = \left[\frac{\partial \mathbf{OP}_{1i}}{\partial \theta_n} \right], \quad \mathbf{J}_{2i} = \left[\frac{\partial \mathbf{OP}_{2i}}{\partial \theta_n} \right]$$
$$\mathbf{J}_{3i} = \left[\frac{\partial \mathbf{OB}_i}{\partial \theta_n} \right], \quad \mathbf{J} = \left[\frac{\partial \mathbf{OP}}{\partial \theta_n} \right]$$
(8)

Figure 7 shows the workspace with the torque of actuator 1 for each position of the workspace of the Delta robot. It should be noted that as the Delta robot that we are studying is symmetrical, the values of the input torques for the actuators are also symmetrical but they are situated in different zones (rotations of ± 120 deg).

The three input torques can be presented by the following expression:

$$\begin{cases}
M_{1\text{bal}}^{\text{st}} \\
M_{2\text{bal}}^{\text{st}} \\
M_{3\text{bal}}^{\text{st}}
\end{cases} = \begin{cases}
M_{1}^{\text{st}} \\
M_{2}^{\text{st}} \\
M_{3}^{\text{st}}
\end{cases} + \mathbf{J}^{T} \begin{cases}
0 \\
0 \\
F
\end{cases} \tag{9}$$

where $M_{i\text{bal}}^{\text{st}}$ is the optimized torque of actuator i (i=1,2,3).

The condition for the minimization of the root-mean-square (rms) value of the torques can be expressed as

$$\sqrt{\frac{\sum_{p=1}^{N}(\sum_{i=1}^{3}(M_{i}^{\mathrm{st}}(x_{p},y_{p},z_{p})+J_{(3i)}(x_{p},y_{p},z_{p})F)^{2})}{N}}\rightarrow\min_{F} \quad (10)$$

where M_i^{st} is the initial torque of the actuator i, N is the number of calculated positions of the robot, $J_{(3i)}$ is the ith column of the third line of matrix \mathbf{J} , i=1,2,3, is the number of the actuator, and x_p , y_p , and z_p are the coordinates of the pth calculated position of the workspace.

For the minimization of the rms value of the torques, it is necessary to minimize the sum,

Journal of Mechanical Design

JULY 2008, Vol. 130 / 072305-5

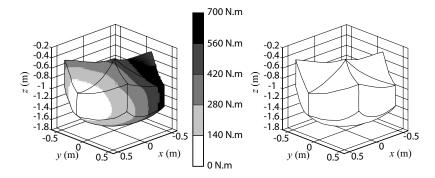

Fig. 7 Input torque 1 for unbalanced (left) and balanced (right) Delta robots

$$\Delta = \sum_{k=1}^{N} \left(\sum_{i=1}^{3} \left(M_i^{\text{st}}(x_p, y_p, z_p) + J_{(3i)}(x_p, y_p, z_p) F \right)^2 \right)$$
 (11)

For this purpose, we shall achieve the condition $\partial \Delta / \partial F = 0$, from which we determine the force

$$F = -\frac{\sum_{k=1}^{N} (\sum_{i=1}^{3} J_{(3i)}(x_{p}, y_{p}, z_{p}) M_{i}(x_{p}, y_{p}, z_{p}))}{\sum_{k=1}^{N} (\sum_{i=1}^{3} J_{(3i)}^{2}(x_{p}, y_{p}, z_{p}))}$$
(12)

Numerical example. For the Delta robot of the SurgiScope®, the parameters are the following (see Fig. 6):

- $l_{A_iB_i} = 0.75 \text{ m}$
- $l_{B,C} = 0.95 \text{ m}$
- m_{1i} =2.3 kg (mass of *i*th arm with center P_{1i})
- m_{2i} =5.2 kg (mass of *i*th parallelogram with center P_{2i})
- m_{3i} =3.1 kg (mass of the joint at point B_i)
- m=79 kg (mass of the platform, joints, and medical device, with center in point P)
- $l_{A_iP1i} = l_{A_iB_i}/2 = 0.375 \text{ m}$ $l_{B_iP2_i} = l_{B_iC_i}/2 = 0.475 \text{ m}$

Thus, the value of the added force for the given parameters is F =931 N.

Figure 7 shows the variations of the input torques for unbalanced and balanced delta robots. The obtained results show that the reduction of the rms value of the input torque is 99.5%. The reduction of the maximum value of the torque is 92%.

The purpose of this study is to develop a reliable mechanism for gravitational force balancing of spatial parallel manipulators. Moreover, it is also tempting to consider the minimization of the torques due to the dynamic loads, i.e., inertia forces.

3.2 Minimization of the Torques Due to the Dynamic Loads (Inertia and Gravitational Forces). The input torque of the *i*th actuator can be expressed as [44]

$$M_i^{\text{dyn}} = \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{\alpha}_i} \right) - \frac{\partial L}{\partial \alpha_i} - \lambda_i A_{i,i+3}, \quad i = 1, 2, 3$$
 (13)

With the added force F, Eq. (13) can be written as

$$M_{i\text{bal}}^{\text{dyn}} = M_i^{\text{dyn}} + B_{i3}A_{i,i+3}F$$
 (14)

where $[B_{ij}]$ is the inverse matrix of matrix A [44] composed by the first three columns only.

We would like to point out that in the case of the dynamic study, the input torques depend on the velocity and acceleration of the platform displacement, and it is impossible to realize an optimization for the whole workspace of the robot (as it was for the static load minimization). Thus, we must define a trajectory in which the input torques will be minimized. The selected trajectory is presented in Fig. 8. The kinematic characteristics of the examined motion are given by the maximum values of the acceleration

and velocity and are presented in Table 2 (factors a and v).

The condition for the minimization of the rms value of the torques can be expressed as

$$\sqrt{\sum_{p=1}^{N} \left(\sum_{i=1}^{3} \left(M_i^{\text{dyn}} + B_{i3} A_{i,i+3} F \right)^2 \right) / N} \to \min_{F}$$
 (15)

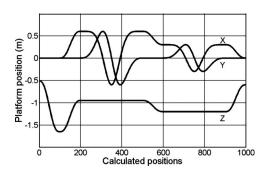

where M_i^{dyn} is the initial torque of the actuator i, N is the number of calculated positions of the robot, and i=1,2,3 is the number of the actuator.

For the minimization of the rms value of the torques, it is necessary to minimize the sum

$$\Delta = \sum_{n=1}^{N} \left(\sum_{i=1}^{3} \left(M_i^{\text{dyn}} + B_{i3} A_{i,i+3} F \right)^2 \right) \to \min_{F}$$
 (16)

For this purpose, we shall achieve the condition $\partial \Delta / \partial F = 0$, from which we determine the force

$$F = -\frac{\sum_{p=1}^{N} (\sum_{i=1}^{3} B_{i3} A_{i,i+3} M_{i}^{\text{dyn}})}{\sum_{p=1}^{N} (\sum_{i=1}^{3} (B_{i3} A_{i,i+3})^{2})}$$
(17)

The output parameters for the selected trajectory

Table 2 Input torques for unbalanced and balanced robots

Maximum values of the acceleration and	Maximun input torque	ii vaido	Balancing force	Gain

$a=0.1 \text{ m/s}^2$ v=0.26 m/s	645	57	956	91
$a=1.05 \text{ m/s}^2$ v=0.79 m/s	652	110	897	83
$a=4.13 \text{ m/s}^2$ v=1.57 m/s	677	326	779	49

072305-6 / Vol. 130, JULY 2008

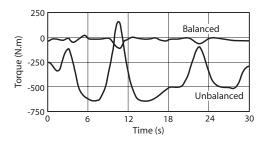

Fig. 9 Input torque 1 for unbalanced and balanced Delta robots

For the examined trajectory with $a=1.05 \text{ m/s}^2$ and v=0.79 m/s, we determine the external force to be F=934 N.

Figure 9 shows the variations of the input torque 1 for the unbalanced and balanced Delta robots (for $a=1.05 \text{ m/s}^2$, v=0.79 m/s when the reduction of the input torques is 83%).

4 Minimization of the Input Torques by a Variable Force Applied to the Platform of the Robot

This section also contains two cases: minimization of the input torques due to the static and dynamic forces.

4.1 Minimization of the Torques Due to the Static Loads (**Gravitational Forces**). The relationship between the actuator input torques and the resultant force can be written as

$$\mathbf{F}^{\text{res}} = \mathbf{J}^{-T} \mathbf{M}^{\text{st}} \tag{18}$$

where $\mathbf{M}^{\text{st}} = \{M_1^{\text{st}} M_2^{\text{st}} M_3^{\text{st}}\}^T$.

This variable force has three components along the X, Y, and Z axes. For minimization of the input torques, we use the component of F^{res} along the Z axis, which is similar to the added force F.

It should be noted that the difference in the minimized torques between the two examined cases (with constant and variable forces) is very small (about 1%). Thus, for the minimization of the static loads, it is better to use constant force. The constant force is easier to create than the variable force.

4.2 Minimization of the Torques Due to the Dynamic Loads (Inertia and Gravitational Forces). The expressions for the input torques are similar to those in the previous case,

$$M_{i\text{bal}}^{\text{dyn}} = M_i^{\text{dyn}} + B_{i3}A_{i,i+3}F \tag{19}$$

The condition for the minimization of the torques at the pth calculated position is formulated as

$$\Delta_p = \sum_{i=1}^{3} (M_i^{\text{dyn}} + B_{i3} A_{i,i+3} F)^2 \to \min_{F_p}, \quad p = 1, \dots, N$$
 (20)

where M_i^{dyn} is the initial torque of the actuator i, N is the number of calculated positions of the simulation, and i=1,2,3 is the number of the actuator.

From the condition $\partial \Delta_p/\partial F_p$ =0, we determine the external force for each position of the trajectory,

$$F_p = -\frac{\sum_{i=1}^{3} (B_{i3} A_{i,i+3} M_i^{\text{dyn}})}{\sum_{i=1}^{3} (B_{i3} A_{i,i+3})^2}, \quad p = 1, \dots, N$$
 (21)

Table 3 presents the maximum values of the torques for three examined cases. It should be noted that in this case also, the increase in the velocity and acceleration leads to the reduction in the efficiency of the minimization.

We would like to draw attention to the fact that the added force F is always vertical and cannot compensate for all effects of the inertia forces along the X and Y axes.

Figure 10 shows the variations of the input torques for the

Table 3 Input torques for unbalanced and balanced robots

Maximum values	Maximun input torque	Gain	
and velocity	Unbalanced	Balanced	(%)
$a=0.1 \text{ m/s}^2$ v=0.26 m/s	645	40	94
$a=1.05 \text{ m/s}^2$ v=0.79 m/s	652	96	85
$a=4.13 \text{ m/s}^2$ v=1.57 m/s	677	262	60

initial and optimized cases (for a=1.05 m/s, v=0.79 m/s when the reduction of the input torques is 85%). It should be noted that these simulations showed that the minimization of the input torques achieved by using a variable force is not very efficient. The difference between two examined cases with constant and variable forces is very small. Taking into account the difficulty involved in the practical realization of the variable force, we can conclude that for the suggested balancing mechanism, it is enough to use the constant force.

5 Increase in the Positioning Accuracy of Spatial Parallel Manipulators Balanced by the Suggested Mechanism

It should be noted that most research papers devoted to the study of parallel manipulators deal with the mechanical structures with rigid links. So, in this case, the position of the platform is considered to be perfectly parallel to the base, and its coordinates are determined from the nominal values of the link lengths. However, in reality, the errors due to the elastic deformations of the mechanical structure of the manipulator change the position and orientation of the platform. Our observation showed that the increase in the platform mass leads to increases in these errors. In this section, it will be shown that the suggested balancing mechanism has a positive influence on the improvement of the positioning accuracy of the parallel robot.

The static rigidity of the Delta robot is defined as the 6×6 symmetrical matrix **K** that maps generalized infinitesimal displacements $\Delta \mathbf{X} = [\delta x \ \delta y \ \delta z \ \delta \phi_x \ \delta \phi_y \ \delta \phi_z]^T$ of the platform to generalized external loads $\mathbf{F} = [F_x \ F_y \ F_z \ M_x \ M_y \ M_z]^T$.

Thus, we have

$$\mathbf{F} = \mathbf{K}\Delta\mathbf{X} \tag{22}$$

With the link parameters given in Table 4 and the payload equal to 70 kg, the positioning errors caused by the elastic deformation

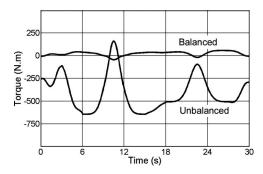

Fig. 10 Input torque 1 for unbalanced and balanced Delta robots

Journal of Mechanical Design

JULY 2008, Vol. 130 / 072305-7

Table 4 Link parameters

Link	Cross-section area (m ²)	Quadratic moment about y (m ⁴)	Quadratic moment about z (m ⁴)	Elastic modulus (E) (GPa)	Poisson coefficient (v)

6 Prototype and Experimental Validation

6.1 Prototype. A prototype has been designed and built for the validation of the obtained results. It was implemented in the structure of the Delta robot of the SurgiScope® provided by the ISIS Company. To design the prototype, the first stage is to find the optimal lengths of the multiloop pantograph linkage, taking into account that it should not collide with the legs of the Delta robot. Then, the appropriate stiffness characteristics of the multiloop pantograph linkage were found by the evolution of the shapes and design concept of links, as well as by successive optimizations based on the finite element analysis.

After assembling the prototype, its static balance was verified by placing it vertically and noting that the mechanism is in equilibrium in any of its configurations. In such a manner, the balancing force for a developed multiloop pantograph linkage was found through experimentation ($F_{B/pantograph}=52$ N). The base of the balancing mechanism was then suspended from the fixed structure of the Delta robot, and its end was connected to the moving platform (Fig. 12). In order to create a balancing force, a counterweight was used. It is obvious that for industrial applications it is better to use pneumatic cylinders or electric actuators with a constant mo-

ment. However, the validation of the obtained results can also be achieved by a counterweight, which develops the same force as a pneumatic cylinder or an electric actuator.

6.2 Experimental Bench. The experimental bench (Fig. 13) is composed of the Delta robot with its control system, a computer to interact with the user and a DSPACE 1103 board. The sampling period is 1 ms (corresponding sampling frequency f_e).

The Delta Robot is composed of three Parvex RX320E dc servo motors with the following main characteristics:

- rated speed: 3000 tr/min and maximum speed: 3900 tr/min
- rated torque (in slow rotation): 1.08 N m
- rated current: 7.8 A and instantaneous maximum current: 20 A
- 100,000 encoder pulses per revolution (resolution: 0.0036 deg)

To show the improvement made in an industrial system by the balancing mechanism, we have preserved the existing industrial control system and used its speed control entries to actuate the motors. The DSPACE 1103 realizes the interface between the PC and the servosystem. This board allows the control of our three motorized axes and has specific entries to which we have directly connected our three incremental encoders. To control the system, the MATLAB/SIMULINK/RTI/CONTROLDESK software has been used.

The robot is controlled by a classical PID law, already included in the industrial control system. We have observed the torque response of the system to a movement composed of a straight line with respect to the **Z** axis and a circle in the space (Fig. 14).

6.3 Experimental Results and Comparative Analysis. The input torques measured for each actuator in different cases are denoted by A, B, C, and D: A, unloaded robot; B, loaded robot (robot with the load of 690 N); C, load balanced robot (balancing by mechanism with a force of 690 N); and D, load and mechanical system balanced robot (balancing by mechanism with a force

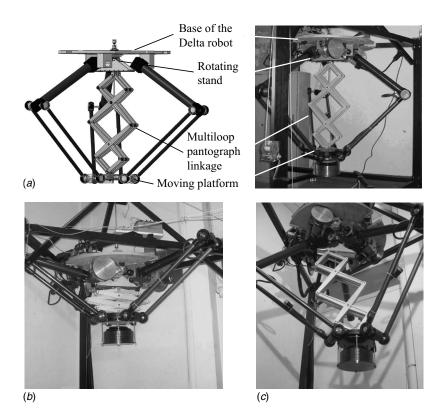

Fig. 12 Computer aided design model and prototype of the balancing mechanism implemented in the structure of the Delta robot

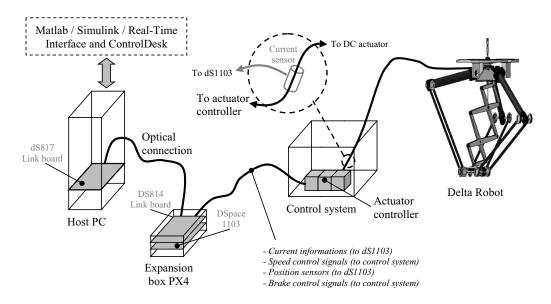

Fig. 13 Experimental bench

of 880 N).

We would like to draw attention to cases C and D. In case C, we have only compensated the load added on the robot platform to obtain the same result as thus obtained when the robot is unloaded. In case D, we have taken into account the mass of the Delta robot links, which gives the best result.

The measured input torques have been taken for two different speeds of the movement (maximal Cartesian acceleration and maximal Cartesian speed). Experiment 1 (E1): 15% of the maximum capacity of the robot to neglect most of the dynamic effects (we consider it as the static mode of operation). Experiment 2 (E2): 100% of the maximum capacity of the robot to observe the improvement for the dynamic mode of operation.

The obtained measurements confirm perfectly the theoretical results (Fig. 15). When balancing is carried out by taking into account only the load on the platform, the results are similar to those obtained for the unloaded robot (cases A and C). When balancing is carried out by taking into account the load on the platform and loads of the robot links, we obtain the lowest values for the input torques (case D).

Tables $\overset{\frown}{0}$ and $\overset{\frown}{7}$ show the reduction of the input torques for E1 and E2.

We can observe that the improvement for actuators 1 and 2 in the quasistatic movement is 77% and that for actuator 3 is 59%. For the dynamic mode of operation, the improvement for actuator 1 is 52%, that for actuator 2 is 56%, and that for actuator 3 is

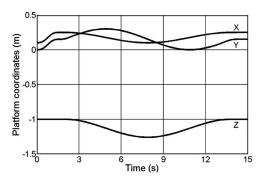

Fig. 14 Selected trajectory for experimental validation of torque minimization

18%

Gains for actuator 3 are quite different from the two others because this one was less solicited by the given trajectory than the two others; i.e., for the given trajectory, the load of the platform on actuator 3 was smaller (see Table 7, case B). So, it is natural that for this actuator, we do not observe a consequent improvement of its torque by the balancing mechanism.

The experimental validation of the suggested balancing approach showed that satisfactory results are achieved and the developed system is fully operational.

The next step of the experimental validation is the estimation of the positioning errors for balanced and unbalanced robots. For this purpose, a trajectory given by the following nine points was chosen (Table 8).

These points are uniformly distributed about a straight line of 800 mm length. To obtain this line physically, a sphere is used, which was moved along a rail (Fig. 16). The position of each point is measured by three dial gauges fixed on the robot platform. The purpose of these measurements is to obtain the positioning errors for unbalanced and balanced Delta robots.

The obtained results are shown in Fig. 17. The abscissa axis corresponds to the unloaded case. Then, the Delta robot was loaded and the relative errors were measured (graph "unbalanced robot"). Finally, the robot was balanced by the suggested mechanism, and relative errors are shown for the "balanced robot." The average rate of the improvement in the relative positioning accuracy with respect to **Z** axis is 93.5%, which corresponds to the value obtained by the numerical simulations.

With regard to the measurement of other positioning and orientation errors, which are caused by the displacement of the platform, we observe that the frame of the robot is insufficiently rigid in a cross-section direction. Taking into account the important mass of the counterweight, it is strongly deformed and leads to significant distortions of the measured parameters.

7 Conclusion

In this paper, a new approach for balancing of spatial parallel manipulators has been presented. It involves connecting a secondary mechanical system to the initial robot, which generates a vertical force applied to the platform of the manipulator. The suggested balancing mechanism is designed on the base of the multiloop pantograph linkage introduced between the robot base and the platform. The minimization of the input torques was car-

Fig. 16 Measuring of the positioning errors for a given straight line trajectory

ried out by constant and variable forces for static and dynamic modes of operation. It was shown that a significant reduction in input torques can be achieved by the suggested balancing mechanism: the reduction of the rms value of the input torque due to the gravitational forces is 99.5% and the maximum value is 92%. The positioning errors of the unbalanced and balanced parallel manipulators are provided. It was shown that the elastic deformations of the manipulator structure due to the payload change the altitude and the inclination of the platform. A significant reduction in these errors is achieved by using the balancing mechanism (from 86.8% to 97.5%). The theoretical results obtained by numerical simulations were confirmed by experimental study carried out by means of the developed prototype mounted on the Delta robot.

It should be noted that the suggested balancing mechanism not only improves the positioning accuracy of the parallel robot, but also sharply reduces stress in its links and efforts in the joints. This system can also be used for the operational safety of robotized medical devices because it can maintain the fixed position of the platform if the parallel robot actuators should accidentally stop.

The suggested balancing approach was demonstrated for the Delta robot but the designed mechanism can be applied to many spatial parallel robots with 3DOF to 6DOF. This type of mechanism is expected to lead to designs that can carry a larger payload and/or reduce energy consumption.

Finally, it should be noted that the proposed balancing mechanism has been patented [45], and additional information is available upon request.
