1. Introduction

A mechanical system with unbalance shaking force/moment transmits substantial vibration to the frame. Thus, a primary objective of the balancing is to cancel or reduce the variable dynamic loads transmitted to the frame and surrounding structures. Different approaches and solutions devoted to this problem have been developed and documented for one degree of freedom mechanisms [1,2]. A new field for their applications is the design of mechanical systems for fast manipulation, which is a typical problem in advanced robotics.

The balancing of a mechanism is generally carried out by two steps: (i) the cancellation (or reduction) of the shaking force and (ii) the cancellation (or reduction) of the shaking moment. Traditionally, the cancellation of the shaking force transmitted to the manipulator frame can be achieved via adding counterweights in order to keep the total centre of mass of moving links stationary [1], via additional structures [1,3] or by elastic components [4].

With regard to the shaking moment balancing of manipulators, the following approaches were developed: (i) balancing by counter-rotations [5–9], (ii) balancing by adding four-bar linkages [10–12], (iii) balancing by creating a redundant mechanism which generates optimal trajectories of moving links [13–15], (vi) balancing by prescribed rotation of the end-effector [16–18], and (vii) balancing by adding an inertia flywheel rotating with a prescribed angular velocity [19,20].

In the present paper we consider a simple and effective balancing method, which allows the considerable reduction of the shaking force of non-redundant manipulators without adding counterweights. It is based on the optimal control of the acceleration of the total mass centre of moving links. To the best of the authors’ knowledge, this problem is addressed for the first time.
2. Minimization of the shaking forces via an optimal motion planning of the total mass centre of moving links

2.1. Definition of the optimal trajectory

The shaking forces $f_{sh}$ of a manipulator can be written in the form:

$$f_{sh} = \sum m_i \ddot{x}_S$$

(1)

where $\sum m_i$ is the total mass of the moving links of the manipulator and $\ddot{x}_S$ is the acceleration of the total mass centre. The classical balancing approach consists in adding counterweights in order to keep the total mass centre of moving links stationary. In this case, $\ddot{x}_S = 0$ for any configuration of the mechanical system. But, as a consequence, the total mass of the manipulator is considerably increased. Thus, in order to avoid this drawback, in the present study, a new approach is proposed, which consists of the optimal control of the total mass centre of moving links. Such an optimal motion planning allows the reduction of the total mass centre acceleration and, consequently, the reduction of the shaking force.

Classically, manipulator displacements are defined considering either articular coordinates $q$ or Cartesian variables $x$. Knowing the initial and final manipulator configurations at time $t_0$ and $t_f$ denoted as $q_0 = q(t_0)$ and $q_f = q(t_f)$, or $x_0 = x(t_0)$ and $x_f = x(t_f)$, in the case of the control of the Cartesian variables, the classical displacement law may be written in the form:

$$q(t) = s_q(t)(q_f - q_0) + q_0$$

(2a)

or

$$x(t) = s_x(t)(x_f - x_0) + x_0$$

(2b)

where $s_q(t)$ and $s_x(t)$ may be polynomial (of orders 3, 5 and higher), sinusoidal, bang-bang, etc. motion profiles [21].

From expression (1), we can see that the shaking force, in terms of norm, is minimized if the norm $\ddot{x}_S$ of the centre of mass acceleration is minimized along the trajectory. This means that if the displacement $x_S$ of the manipulator centre of masses is optimally controlled, the shaking force will be minimized. As a result, the first problem is to define the optimal trajectory for the displacement $x_S$ of the manipulator centre of masses.

For this purpose, let us consider the displacement $x_S$ of a point $S$ in the Cartesian space. First, in order to minimize the centre of mass acceleration, the length of the path followed by $S$ should be minimized, i.e. point $S$ should move along a straight line passing through its initial and final positions, denoted as $x_{S0}$ and $x_{Sf}$, respectively.

![Motion profiles](image_url)

Fig. 1. Motion profiles used for the shaking force minimization.
Then, the motion profile used on this path should be optimized. It is assumed that, at any moment during the displacement, the norm of the maximal admissible acceleration the point \( S \) can reach is constant and denoted as \( \ddot{x}_S^{\text{max}} \). Taking this maximal value for the acceleration into consideration, it is known that the motion profile that minimizes the time interval \((t_0, t_f)\) for going from position \( x_0 = X(0) \) to position \( x_d = X(t_f) \) is the “bang-bang” profile [21], given by (Fig. 1A)

\[
\begin{align*}
    x_S(t) &= s(t)(x_d - x_0) + x_0 \\
    x_S(t) &= \dot{s}(t)(x_d - x_0) \\
    x_S(t) &= \ddot{s}(t)(x_d - x_0)
\end{align*}
\]

with

\[
\ddot{s}(t) = \frac{1}{|x_d - x_0|} \begin{cases} 
    \ddot{x}_S^{\text{max}} & \text{for } t \leq (t_f - t_0)/2 \\
    -\ddot{x}_S^{\text{max}} & \text{for } t \geq (t_f - t_0)/2.
\end{cases}
\]

Consequently, if the time interval \((t_0, t_f)\) for the displacement between positions \( x_0 \) and \( x_d \) is fixed, the “bang-bang” profile is the trajectory that minimizes the value of the maximal acceleration \( \ddot{x}_S^{\text{max}} \). Thus, in order to minimize \( ||x_S|| \) for a displacement during the fixed time interval \((t_0, t_f)\), the “bang-bang” profile has to be applied on the displacement \( x_S \) on the manipulator total mass centre.

2.2. Observations about the modification of the optimal trajectory for taking into account the actuators properties

It should be mentioned that the given “bang-bang” profile (Fig. 1A) is based on theoretical considerations. In reality, the actuators are unable to achieve discontinuous efforts. Therefore, this motion profile should be modified by a trapezoidal profile (Fig. 1B) in order to take into account the actuators properties in terms of maximal admissible effort variations.

For a given time interval \((t_0, t_f)\), the trapezoidal profile, as we define it, is characterized by two parameters: \( t_1, t_2 \) (Fig. 1B). In order to find the optimal values for \( t_1 \) and \( t_2 \), the following problem should be considered:

\[
\ddot{x}_S^{\text{max}} \rightarrow \min_{t_1, t_2}
\]

under the constraints

\[
\max \left| \frac{d\tau_i}{dt} \right| \leq (\dot{\tau}_i)_{\text{max}}
\]

where \( \tau_i \) is the input effort of the actuator \( i \) and \((\dot{\tau}_i)_{\text{max}}\) the maximal admissible input effort variation for the actuator \( i \). This problem is highly non linear, therefore it can be solved by numerical optimization methods. It should be mentioned that in the illustrative examples given in Section 3, the trapezoidal profile taking into account the actuators properties has been found using the optimisation function “fgoalattain” of Matlab.

2.3. Expression of the manipulator coordinates as a function of the mass centre parameters

Once the displacement of the manipulator centre of masses is defined, the second problem is to find the articular (or Cartesian) coordinates corresponding to this displacement. For this purpose, let us consider a manipulator composed of \( n \) links. The mass of the link \( i \) is denoted as \( m_i \) (\( i = 1, \ldots, n \)) and the position of its centre of masses as \( x_{si} \). Once the articular coordinates \( q \) or Cartesian variables \( x \) are known, the values of \( x_{si} \) may easily be obtained using the manipulator kinematics relationships. As a result, the position of the manipulator centre of masses, defined as

\[
x_S = \frac{1}{m_{\text{tot}}} \sum_{i=1}^{n} m_i x_{si}, \text{ where } m_{\text{tot}} = \sum_{i=1}^{n} m_i
\]
may be expressed as a function of \( x \) or \( q \). But, in order to control the manipulator, the inverse problem should be solved, i.e. it is necessary to express variables \( q \) or \( x \) as a function of \( x_S \). Here, two cases should be distinguished:

(i) \( \dim(x_S) = \dim(q) \), i.e. the manipulator has got as many actuators as controlled variables for the displacements \( x_S \) of the centre of masses (two variables for planar cases, three variables for spatial problems). In such case, the variables \( q \) or \( x \) can be directly expressed as a function of \( x_S \) using Eq. (7), i.e. \( q = f(x_S) \).

(ii) \( \dim(x_S) < \dim(q) \), i.e. the manipulator has got more actuators than controlled variables. In such case, the problem is under-determined as there are more parameters in variables \( q \) or \( x \) than in \( x_S \). In order to solve it, let us consider that \( p_0 \) parameters of vector \( q_0 \) (or \( x_0 \)) and \( pf \) parameters of vector \( q_f \) (or \( x_f \)) are fixed. In a first task, it is necessary to define the \( m-p_0 \) and \( m-pf \) other parameters of the initial and final manipulator configurations \( (m = \dim(q)) \). The way to fix it is to find the manipulator initial and final configurations, taking into account the \( p_0 \) initial and \( pf \) final fixed parameters, that will allow minimizing the norm of the vector \( x_S - x_{0f} \), i.e. the length of the displacement of the manipulator centre of masses. Then, the second task is to choose \( m-k \) articular variables among the \( m \) possible of vector \( q \) \( (k = \dim(x_S)) \). These \( m-k \) variables, denoted as \( q_{m-k} \) will be controlled using some classical displacement law given in Eqs. \( (2a) \) and \( (2b) \) or can be used in order to minimize some other performance criteria, such as the shaking moments or some other interesting performance criterion (see Section 3.2). The \( k \) other variables, denoted as \( q_k \), should be expressed as a function of \( X_S \) and \( q_{m-k} \) using Eq. (7), i.e. \( q_k = f(x_S, q_{m-k}) \).

In order to demonstrate the proposed balancing method, two illustrative examples are given in the following section.

3. Illustrative examples

3.1. The planar 2R serial manipulator

Let us consider the shaking force minimization of a 2R serial manipulator (Fig. 2). This manipulator is controlled using two rotary actuators having two input parameters which are denoted as \( q_1 \) and \( q_2 \). For simulations the following parameters have been used:

- \( l_{OA} = 0.5 \) m, \( l_{AB} = 0.3 \) m, where \( l_{OA} \) and \( l_{AB} \) are the lengths of segments \( OA \) and \( AB \), respectively;
- \( r_1 = 0.289 \), where \( l_{OS_1} = r_1 \ l_{OA} \) and \( r_2 = 0.098 \), where \( l_{AS_2} = r_2 \ l_{AB} \), \( l_{OS_1} \) and \( l_{AS_2} \) being the lengths of segments \( OS_1 \) and \( AS_2 \), respectively.

The mass and inertia parameters are:

- \( m_1 = \) 24.4 kg and \( m_2 = \) 8.3 kg, where \( m_i \) is the mass of element \( i \) \((i = 1, 2)\);
- \( m_{\text{tool}} = \) 5 kg, where \( m_{\text{tool}} \) is the payload;
- \( l_1 = 1.246 \) kg.m² and \( l_2 = 0.057 \) kg.m², where \( l_i \) is the axial moment of inertia of element \( i \).
Let us now express the articulated joint positions $q = [q_1, q_2]^T$ as a function of the position $x_S$ of the manipulator centre of masses. From Eq. (7), we obtain:

$$x_S = \left[ \begin{array}{c} x_S \\ y_S \end{array} \right] = \frac{m_1 r_1 l_{OA}}{m_{tot}} \left[ \begin{array}{c} \cos q_1 \\ \sin q_1 \end{array} \right] + \frac{m_2}{m_{tot}} \left[ l_{OA} \left[ \begin{array}{c} \cos q_1 \\ \sin q_1 \end{array} \right] + r_2 l_{AB} \left[ \begin{array}{c} \cos(q_1 + q_2) \\ \sin(q_1 + q_2) \end{array} \right] \right]$$

$$\cdots + \frac{m_{tool}}{m_{tot}} \left[ l_{OA} \left[ \begin{array}{c} \cos q_1 \\ \sin q_1 \end{array} \right] + l_{AB} \left[ \begin{array}{c} \cos(q_1 + q_2) \\ \sin(q_1 + q_2) \end{array} \right] \right] \right]$$

This relationship leads to:

$$(x_S - l_{eq1} \cos q_1)^2 + (y_S - l_{eq1} \sin q_1)^2 - l_{eq2}^2 = 0$$

where $l_{eq1} = (m_1 r_1 + m_2 + m_{tool}) l_{OA} / m_{tot}$ and $l_{eq2} = (m_2 r_2 + m_{tool}) l_{AB} / m_{tot}$.

Fig. 4. Manipulator end-effector displacements along the trajectory $P_5P_9$: (A) for case 1 and (B) for cases 2 and 3.
Replacing \( \cos q_1 \) and \( \sin q_1 \) by \((1 - t_1^2)/(1 + t_1^2)\) and \(2t_1/(1 + t_1^2)(t_1 = \tan(q_1/2))\), respectively, and developing Eq. (9), we obtain:

\[
q_1 = 2 \tan^{-1} \left( \frac{-b \pm \sqrt{b^2 - c^2 + a^2}}{c-a} \right)
\]

where

\[
a = -2t_{eq1}x_5, \quad b = -2t_{eq1}y_5 \quad \text{and} \quad c = x_5^2 + y_5^2 + t_{eq1}^2 - t_{eq2}^2.
\]

In Eq. (10), the sign “±” stands for the two possible working modes of the manipulator (for simulations, the working mode with the “+” sign is used). Once \( q_1 \) is known, \( q_2 \) may easily be found from Eq. (8):

\[
q_2 = \tan^{-1} \left( \frac{y_5 - t_{eq1} \sin q_1}{x_5 - t_{eq1} \cos q_1} \right) - q_1.
\]

Let us now test the proposed approach. In order to show the efficiency of this optimal planning, several trajectories are tested. These trajectories are defined as follows. First, the maximal inscribed square inside of the workspace is found (Fig. 3). For this manipulator, it is a square of length 0.55 m, of which centre \( E \) is located at \( x = 0 \) m and \( y = 0.475 \) m. Then, in order to avoid problems due to the proximity of singular configuration, the tested zone is restricted to a square centred in \( E \) of edge length equal to 0.45 m (in grey on Fig. 3). Finally, we discretize each edge into four segments delimited by the points \( P_i \) (i = 1 to 16). The tested trajectories will be the segments \( P_1P_{13}, P_2P_{12}, P_3P_{11}, P_4P_{10}, P_5P_9, P_{15}P_7, P_1dP_3 \) and \( P_{13}P_9 \). Each trajectory will have a duration of 0.5 s and, for each trajectory, three different kinds of motion profiles are applied:

1. a fifth order polynomial profile is applied on the displacement of the manipulator end-effector;
2. a “bang-bang” profile is applied on the displacement of the manipulator centre of masses;
3. a trapezoidal acceleration variation is applied on the displacement of the manipulator centre of masses, taking into account that, for each actuator, the input effort variation is limited by \( 3 \times 10^4 \) Nm/s.

The displacements of the end-effector and manipulator links centre of masses for the trajectory \( P_5P_9 \) are shown in Fig. 4. These trajectory parameters are implemented into ADAMS software and the variations of shaking forces are computed. Fig. 5 presents the shaking force transmitted by the manipulator for trajectory \( P_5P_9 \). The obtained results for the whole paths are summarized in

**Table 1**

Maximal values of the shaking force norm for the tested trajectories of the 2R serial manipulator.
Table 1. It is shown that the optimal trajectory planning ("bang-bang profile") allows the reduction of the shaking force from 36% up to 76.7%. Moreover, it appears that for given actuator parameters, the minimizations obtained in the cases of the "bang-bang" and trapezoidal profiles are very close (less than 1%). It is due to the fact that the actuators can apply high input effort variations during a displacement. However, such a result depends on the actuator power capacity and it will be variable for each type of actuator.

Obviously, the rate of reduction depends on the design parameters of the robot. For each system, it will be different.

Let us now consider the second example.

3.2. The planar 3R serial manipulator

This manipulator is controlled using three rotary actuators (Fig. 6), with three input parameters which are denoted as \( q_1, q_2 \) and \( q_3 \). The link parameters are the following:

- \( l_{OA} = 0.5 \text{ m}, \ l_{AB} = 0.3 \text{ m}, \ l_{BC} = 0.1 \text{ m} \), where \( l_{OA}, \ l_{AB} \) and \( l_{BC} \) are the lengths of segments \( OA, AB \) and \( BC \), respectively;
- \( r_1 = 0.289 \), where \( l_{OS1} = r_1 \ l_{OA} \), \( r_2 = 0.098 \), where \( l_{AS2} = r_2 \ l_{AB} \), and \( r_3 = 0.5 \), where \( l_{BS3} = r_3 \ l_{BC} \), \( l_{OS1}, \ l_{AS2} \) and \( l_{BS3} \) being the lengths of segments \( OS_1, AS_2 \) and \( BS_3 \), respectively.

Its mass and inertia parameters are:

- \( m_1 = 24.4 \text{ kg}, \ m_2 = 8.3 \text{ kg} \) and \( m_3 = 2 \text{ kg} \), where \( m_i \) is the mass of element \( i \) (i = 1, 2, 3);
- \( m_{tool} = 5 \text{ kg} \), where \( m_{tool} \) is the payload;
- \( I_1 = 1.246 \text{ kg.m}^2, \ I_2 = 0.057 \text{ kg.m}^2 \) and \( I_3 = 0.025 \text{ kg.m}^2 \), where \( I_i \) is the axial moment of inertia of element \( i \).
In order to have the possibility to control the manipulator, let us express the relation between the articulated joint positions \(q = [q_1, q_2, q_3]^T\) and the position \(x_S\) of the manipulator centre of masses. From Eq. (7), we obtain:

\[
x_S = \begin{bmatrix} x_S \\ y_S \end{bmatrix} = \frac{m_1 l_{OA}}{m_{tot}} \begin{bmatrix} \cos q_1 \\ \sin q_1 \end{bmatrix} + \frac{m_2}{m_{tot}} l_{OA} \begin{bmatrix} \cos q_1 + q_2 \\ \sin(q_1 + q_2) \end{bmatrix} + \frac{m_3}{m_{tot}} l_{OA} \begin{bmatrix} \cos q_1 + q_3 \\ \sin(q_1 + q_3) \end{bmatrix}
\]

\[
+ \frac{r_1}{C_{20}/C_{21}} \begin{bmatrix} \cos q_1 \\ \sin q_1 \end{bmatrix} + \frac{r_2}{C_{20}/C_{21}} \begin{bmatrix} \cos(q_1 + q_2) \\ \sin(q_1 + q_2) \end{bmatrix} + \frac{r_3}{C_{18}/C_{19}} \begin{bmatrix} \cos q_1 + q_3 \\ \sin(q_1 + q_3) \end{bmatrix}
\]

where \(\phi = q_1 + q_2 + q_3\).

In Eq. (13), there are three unknowns \(q_1, q_2, q_3\) for two fixed parameters \(x_S\) and \(y_S\). Therefore, as mentioned in Section 2, a way to solve this problem is to consider that one parameter, for example \(\phi\), is used to minimize some objective function. Then the expressions of \(q_1, q_2\) and \(q_3\) can be found as a function of \(x_S, y_S\) and \(\phi\). In the remainder of the paper, angle \(\phi\) is used in order to minimize the shaking moment \(m_{sh}\) of the robot. Obviously, if necessary, it can be replaced by another criterion, such the energy, the torques, etc.

---

**Fig. 8.** Manipulator end-effector displacements along the trajectory \(P_1P_7\): (A) for case 1 and (B) for optimal cases 2 and 3.
Eq. (13) leads to the following loop closure equation:

\[
\left( (x_s - l_{eq1} \cos \phi) - l_{eq1} \cos q_1 \right)^2 + \left( (y_s - l_{eq1} \sin \phi) - l_{eq1} \sin q_1 \right)^2 - l_{eq2}^2 = 0
\]  

where 

\[
l_{eq1} = (m_1 r_1 + m_2 + m_3 + m_{tool}) l_{OA}/m_{tot}, \quad l_{eq2} = (m_2 r_2 + m_3 + m_{tool}) l_{AB}/m_{tot} \quad \text{and} \quad l_{eq3} = (m_3 r_3 + m_{tool}) l_{BC}/m_{tot}.
\]

Replacing \( \cos q_1 \) and \( \sin q_1 \) by \((1 - t_1^2)/(1 + t_1^2)\) and \(2t_1/(1 + t_1^2)\)\((t_1 = \tan(q_1/2))\), respectively, and developing Eq. (14), we obtain:

\[
q_1 = 2 \tan^{-1} \left( \frac{-b \pm \sqrt{b^2 - c^2 + a^2}}{c-a} \right)
\]  

where

\[
a = -2 l_{eq1} \left( x_s - l_{eq3} \cos \phi \right),
\]

\[
b = -2 l_{eq1} \left( y_s - l_{eq3} \sin \phi \right),
\]

\[
c = \left( x_s - l_{eq3} \cos \phi \right)^2 + \left( y_s - l_{eq3} \sin \phi \right)^2 + l_{eq1}^2 - l_{eq2}^2.
\]

In expression (15), the sign “±” stands for the two possible working modes of the manipulator (for simulations, the working mode with the “+” sign is used). Once \( q_1 \) is known, \( q_2 \) and \( q_3 \) may easily be found from Eq. (13):

\[
q_2 = \tan^{-1} \left( \frac{y_s - l_{eq3} \sin \phi - l_{eq1} \sin q_1}{x_s - l_{eq3} \cos \phi - l_{eq1} \cos q_1} \right) - q_1
\]

\[
q_3 = \phi - q_1 - q_2.
\]

Let us now test the proposed approach with this manipulator. The tested trajectories are defined as follows. First, the maximal inscribed square inside of the workspace, for any end-effector orientation, is found (Fig. 7). For this manipulator, it is a square of length 0.375 m, of which centre \( E \) is located at \( x = 0 \) m and \( y = 0.487 \) m. Then, in order to avoid problems due to the proximity of

skeletal configuration, the tested zone is restricted to a square centred in E of edge length equal to 0.3 m (in grey on Fig. 7). Finally, we discretize each edge into four segments delimited by the points \(P_i\) (\(i = 1\) to 16). The tested trajectories will be the segments \(P_1P_{13}, P_2P_{12}, P_3P_{11}, P_4P_{10}, P_5P_9, P_6P_8, P_7P_6\) and \(P_9P_7\). It should be noted that in this case there is an independent parameter \(\phi\), which can be defined from complementary condition describing the orientation of the end-effector. For numerical simulations, it is chosen to begin the tested trajectories with an end-effector orientation \(\phi_0 = 0^\circ\) and to finish it at \(\phi_f = 120^\circ\).

The simultaneous minimization of the shaking force and the shaking moment cannot be done without using an optimization algorithm in order to solve the following problem:

\[
\max \left( m^h \right) \rightarrow \min_{\phi}
\]

under the constraints

\[
\phi(t_0) = \phi_0, \quad \phi(t_f) = \phi_f \tag{20a}
\]

\[
\dot{\phi}(t_0) = \dot{\phi}(t_f) = 0 \tag{20b}
\]

\[
\ddot{\phi}(t_0) = \ddot{\phi}(t_f) = 0 \tag{20c}
\]

\[
X_c(t_0) = X_{50}, \quad X_c(t_f) = X_{5f} \tag{20d}
\]

Several motion profiles for \(\phi\) can be tested. Here it is proposed to use polynomials. Our observations showed that the polynomial function that makes it possible to obtain optimal results is of degree 8.

Each trajectory will have a duration of 0.5 s and, for each trajectory three different kinds of motion profiles are applied:

1. a fifth order polynomial profile is applied on the displacement (translation and rotation) of the manipulator end-effector;
2. a “bang-bang” profile is applied on the displacement of the manipulator centre of masses and the angle \(\phi\) is optimized in order to minimize the shaking moment;
3. a trapeze acceleration profile is applied on the displacement of the manipulator centre of masses, taking into account that, for each actuator, the input effort variation is limited by \(3 \times 10^4\) Nm/s; the trajectory for angle \(\phi\) optimized in the previous case is used in order to compute the actuator displacements.

### Table 3
Maximal values of the shaking moment for the tested trajectories on the 3R serial manipulator.

Fig. 10. Variations of the shaking moment in the case of the trajectory \(P_1P_{13}\): case 1 (black full line), case 2 (black dashed line) and case 3 (grey full line).
The displacements of the end-effector and manipulator links centre of masses for the trajectory $P_{15}P_7$ are shown in Fig. 8. Fig. 9 presents the shaking force and Fig. 10 the shaking moment for the path $P_{15}P_7$. The obtained results for the whole paths are summarized in Tables 2 and 3. It is shown that the optimal trajectory planning ("bang-bang" profile) allows the reduction of the shaking forces from 48% up to 62.2%. Moreover, with a simultaneous optimal control of angle $\phi$, the shaking moment can be reduced from 37.2% up to 61%.

As previously mentioned, these results depend on the design parameters of the used robot. For another manipulator, they will be different. But, in any case the shaking force and moment shall be decreased.

3.3. Observations about input torques

The main drawback of the shaking force balancing by counterweights is the increase of the inertia of moving links caused by adding masses, and consequently, the increase of input torques. The advantage of the suggested balancing method is in the fact that the shaking forces are only reduced by optimal control of moving links, without adding counterweights. It results in the fact that the input torques are considerably lower than in the case of balancing by counterweights. To illustrate this advantage for examined 2R serial manipulator, three kinds of simulations have been carried out using dynamic simulation software: (a) unbalanced manipulator carrying out a straight line trajectory along $P_5P_9$ (Fig. 4) using a fifth order polynomial motion profile; (b) manipulator balanced by counterweights along the same trajectory; (c) manipulator controlled via optimal centre of mass displacement.

**Fig. 11.** Manipulator input torques for trajectory $P_5P_9$ corresponding to the three simulated models: (i) unbalanced manipulator carrying out a straight line trajectory of the end-effector using a fifth order polynomial motion profile (black full line); (ii) manipulator balanced by counterweights along the same trajectory (grey full line); (iii) manipulator controlled via optimal centre of mass displacement (black dashed line).

The displacements of the end-effector and manipulator links centre of masses for the trajectory $P_{15}P_7$ are shown in Fig. 8. Fig. 9 presents the shaking force and Fig. 10 the shaking moment for the path $P_{15}P_7$. The obtained results for the whole paths are summarized in Tables 2 and 3. It is shown that the optimal trajectory planning ("bang-bang" profile) allows the reduction of the shaking forces from 48% up to 62.2%. Moreover, with a simultaneous optimal control of angle $\phi$, the shaking moment can be reduced from 37.2% up to 61%.

As previously mentioned, these results depend on the design parameters of the used robot. For another manipulator, they will be different. But, in any case the shaking force and moment shall be decreased.

3.3. Observations about input torques

The main drawback of the shaking force balancing by counterweights is the increase of the inertia of moving links caused by adding masses, and consequently, the increase of input torques. The advantage of the suggested balancing method is in the fact that the shaking forces are only reduced by optimal control of moving links, without adding counterweights. It results in the fact that the input torques are considerably lower than in the case of balancing by counterweights. To illustrate this advantage for examined 2R serial manipulator, three kinds of simulations have been carried out using dynamic simulation software: (a) unbalanced manipulator carrying out a straight line trajectory along $P_5P_9$ (Fig. 4) using a fifth order polynomial motion profile; (b) manipulator balanced by counterweights along the same trajectory; (c) manipulator controlled via optimal centre of mass displacement between points $P_5$ and $P_9$.

---

1 The counterweights are located at 0.2 m and 0.35 m from the joints centres $A$ and $O$, respectively.
The obtained results are given in Fig. 11. The software simulations showed that in comparison with mass balanced manipulator a 92% reduction in input torque is achieved, and, in comparison with unbalanced manipulator a 73% reduction in input torque is achieved.

Finally, we would like to mention that the method proposed in this paper focused exclusively on the force balancing because it is carried out by optimisation of the trajectory of the manipulator’s centre of mass. However, as was shown above, it also allows the reduction of the shaking moment and the input torques. Such a result has been observed for many simulated manipulators. But it is not possible to pretend in any way that this will be true for any manipulator.

4. Conclusions

In this paper, we have presented a new approach, based on an optimal trajectory planning, which allows the considerable reduction of the shaking force. This simple and effective balancing method is based on the optimal control of the acceleration of the total mass centre of moving links. The trajectories of the total mass centre of moving links are defined as straight lines and are parameterized with “bang-bang” profile. Such a control approach allows the reduction of the maximum value of the centre of mass acceleration and, consequently, the reduction in the shaking force. It should be mentioned that such a solution is also very favourable for reduction of input torques because it is carried out without adding counterweights. The proposed balancing method has been illustrated via two examples. The numerical simulations showed that considerable reduction in shaking force and input torques were achieved.
